ABSTRACT

MDA (multiple discriminant analysis) has been found useful in predicting the probability of operationally critical airfield ceiling and visibility conditions. One part of the discriminant procedure requires at the outset a rather lengthy computation by machine to estimate these probabilities. While the operational use of the method takes much less effort, the time needed initially on a large scale computer may be inordinate when many elements, time periods, and geographical locations are being considered. This technical report discusses a prediction technique, REEP (regression estimation of event probabilities), which resulted from attempts to make MDA more efficient. Comparative studies between REEP and MDA are included as well as other experimentations performed using the REEP procedure. Recommendations for future work on the technique are also given.

1.0 INTRODUCTION

The objective of this task was to develop, in the MDA (multiple discriminant analysis) framework, a method which would produce medium range ceiling and visibility forecasts efficiently. The original plan was to investigate the use of a multivariate statistical procedure called canonical correlation--discriminant analysis being a special case of canonical correlation. By incorporating a feature which screened predictors in canonical correlation, it was expected that more than one predictand could be processed simultaneously with a resulting saving in computer time.

Work on screening canonical correlation was proceeding satisfactorily until it was found that a technique subsequently called REEP (regression estimation of event probabilities) possessed even more desirable computational features. It was later discovered that the REEP technique had appeared in the literature in 1955, Lund [1], (see also Lund [2]). In addition, work related to this approach has been published by Cox [3, 4] and by Warner [5].

This technical report consists of 1) a discussion of the REEP technique, 2) the results of a comparative study between REEP and MDA, 3) the results from a series of experiments investigating various aspects of the REEP procedure, 4) the results from experiments performed to study the effect of modifying the form of the predictor variables by means of Boolean expressions, and 5) discussion and recommendations for future study.

2.0 THE REEP PROCEDURE

Consider the problem of estimating the probability distribution over a set of G mutually exclusive and exhaustive groups where the groups are defined for a specific predictand. The statistical technique of discriminant analysis may be used to estimate probability distributions of this type [6]. The suggested approach for estimating the group probabilities, when the underlying density functions are unknown, is that of Fix and Hodges. This approach requires the computation of "distances" in the discriminant space between a new observation and each observation of the developmental sample. The set of k close neighbors is then used to estimate the group probabilities.

The REEP procedure may be thought of as an alternative to the Fix-Hodges method employed in MDA. Or, more appropriately, it can be viewed as a self-contained statistical prediction method. The following is a description of the REEP procedure:

Perform a series of multiple regressions on G zero-one dependent variables, Y_1, \dots, Y_G , where each dependent variable is associated with one of G predictand groups. The independent variables, X_1, \dots, X_r , are taken to be the same throughout each of the G regressions. The object of this series of regressions is to obtain the least squares estimate of the A 's in the following equations:

$$E(Y_1 | \underline{X}) = \sum_{s=0}^r A_{1s} X_s$$

$$E(Y_2 | \underline{X}) = \sum_{s=0}^r A_{2s} X_s$$

⋮

$$E(Y_G | \underline{X}) = \sum_{s=0}^r A_{Gs} X_s$$

where $X_0 = 1$

All of the conditional distributions, $f(Y_g | \underline{X})$, $g=1, \dots, G$, are Bernoulli distributions (zero-one) and on a single trial the expectation is equal to the probability that $Y_g = 1$. Thus the regression functions give least squares estimates of the group probabilities, \hat{P}_g ($g=1, \dots, G$).

These estimates possess certain desirable and certain undesirable properties:

Desirable

1) The estimates add to unity, i.e., $\sum_{g=1}^G \hat{P}_g = 1$.

2) The estimates essentially minimize the Brier-Allen \bar{P} score,

$$\text{i.e., } \sum_{i=1}^N \sum_{g=1}^G (Y_{ig} - \hat{P}_{ig})^2.$$

Undesirable

1) The estimates are not bounded by 0 and 1.

An intuitively reasonable approach and the one used to remedy this undesirable property is to renormalize the estimates by: a) setting all negatives equal to zero, b) setting all estimates greater than one equal to one, and c) divided each by the resulting overall sum.

3.0 REEP PREDICTOR SELECTION

A predictor selection procedure has been incorporated into the REEP procedure similar to that used in regression and MDA [6], namely:

Out of a set of P possible predictors $X^{(1)}$ is selected such that in the developmental sample it contributes most significantly with regard to one of the G predictands. That is, out of the G possible F distribution statistics the predictor $X^{(1)}$ has one of these computed statistics larger than any one of the G computed for the remaining $P-1$ predictors.

In a similar manner, a second predictor $X^{(2)}$ is selected from the $P-1$ remaining predictors when considered in conjunction with $X^{(1)}$. Selection continues until r predictors $X^{(1)}, X^{(2)}, \dots, X^{(r)}$ have been chosen; r is determined such that $X^{(r+1)}$ is not satisfactorily significant. The significance criterion has been designed similar to that used in screening regression and MDA (see page 13, reference [6]). Namely, compare the G possible computed F statistics, at any of the r selection stages, with a critical value of F_{α} , where the size α of the test is $\frac{1}{20 [P - (S-1)]}$. The

value S denotes the selection stage number or equivalently the number of predictors thus far selected. Tests must still be performed to confirm its applicability, however.

4.0 EXPERIMENTATION

A number of experiments were performed to test certain aspects of the REEP procedure. The complete list of experiment titles is given below.

	<u>Title</u>	<u>Page</u>
<u>Experiment 1</u>	- Comparison Between MDA and REEP (Atlantic City Airport).	7
<u>Experiment 1A</u>	- Comparison Between MDA and REEP (Offutt AFB, Nebraska).	25

<u>Experiment 7</u>	- Single-Station Predictors: Raw Dummies and Boolean Combinations.	106
<u>Experiment 8</u>	- Combination of Selected Predictors from Network and Single-Station Boolean.	129

EXPERIMENT 1. Comparison Between MDA and REEP (Atlantic City Airport)

Purpose

To compare the results of short range ceiling and visibility predictions using the MDA technique and the REEP technique. In the event REEP compares favorably with MDA it might, because of its computational efficiency, be used in place of MDA for forecasting ceiling and visibilities.

Procedure

A test of the REEP technique was made by comparing independent sample predictions of ceiling and visibility using REEP and MDA. Each technique was allowed to select predictors and generate probability forecasts independently. Predictions were made for two stations, Atlantic City Airport, New Jersey and Offutt AFB, Nebraska. (See Experiment 1A for Offutt.)

Predictands

The five operationally significant categories of ceiling and visibility at Atlantic City Airport, New Jersey for the forecast intervals of three and seven hours define the four predictands for which the techniques are compared (see Table 1-1). The specifications for each predictand are given in Table 1-2.

Predictors

Seven meteorological elements at 13 predictor stations (see Figure 1-1) plus the time of day (TOD) and day of year (DOY) variables were transformed into dummy (zero-one) variables (see Tables 1-3 and 1-4). This set of 423 dummy predictors was used as possible predictors for all four predictands.

Data Sample

Standard hourly airways surface observations covering the 10 year period, 1 January 1949 to 31 December 1958, furnished the data for this study. There are 87,672 hours in the 10 years from 1949 through 1958. This is too many to use efficiently; besides not all hours are needed because of the serial correlation present in meteorological variables. The amount of data was reduced by a three-stage process:

- (a) Any variable not observed for a substantial portion of the 87,672 hours was eliminated. A variable was also eliminated if the frequency distribution of its error vector exhibited a bias with regard to hour of day or month of year.
- (b) Those hours were eliminated for which any one of the variables was missing or failed to pass a gross-error check.
- (c) A random selection of the remaining hours was made to select 10,000 cases.

Results

The four sets of predictors selected by MDA and REEP respectively are given in Tables 1-5a to 1-5d as well as the REEP regression equation coefficients for each group of the predictand. Contingency tables (see Tables 1-6a to 1-6d) show the forecast-versus-observed frequencies for persistence, MDA, and REEP. The number of correct forecasts (hits) and the Brier and Allen \bar{P} scores as well as the individual group contributions to the overall \bar{P} score are given below each contingency table. The number of hits and the overall \bar{P} scores are summarized in Table 1-7 by predictand.

Conclusions

See Experiment 1A.

EXPERIMENT 1A. Comparison Between MDA and REEP (Offutt AFB, Nebraska)

The Purpose and the Procedure are the same as those in Experiment No. 1.

Predictands

Visibility at Offutt AFB was divided into four and ceiling into five operationally significant categories (see Table 1A-1) for the following four predictands: CIG + 3 hours, CIG + 7 hours, VIS + 3 hours, and VIS + 7 hours. The specifications of the predictands are tabulated in Table 1A-2.

Predictors

As in Experiment 1, seven meteorological elements at the 13 predictor stations constituted the Offutt AFB network (see Figure 1A-1), plus the time of day and day of year variables. These were then transformed into 423 dummy variables (see Tables 1A-3 and 1A-4).

Data Sample

A data sample containing 10,000 observations was selected at random from the ten year period, 1 January 1949 to 31 December 1958. The developmental sample from the first eight years contained 7668 observations, and the verification sample from the last two years contained 2332 observations.

Results

The four sets of predictors selected by MDA and REEP are shown in Tables 1A-5a to 1A-5d in addition to the REEP regression coefficients for each group of the predictand. The contingency tables (see Tables 1A-6a to 1A-6d) give the forecast-versus-observed frequencies for

12

persistence, MDA, and REEP. The number of hits, the \bar{P} scores, and the individual group contributions to the \bar{P} score are also shown. Table 1A-7 summarizes the number of correct forecasts and the overall \bar{P} scores.

Conclusions

1) In the Atlantic City experiment (Experiment 1) the selected predictors for REEP and MDA are both alike in numbers and in kind. However, in the Offutt experiment (Experiment 1A) this is not the case. There are many more predictors selected as significant in REEP. This is due to two adjustable factors introduced into the REEP computer program for the Offutt experiment but not for the Atlantic experiment.

The first of these is that in REEP each group can be assigned its own effective degrees of freedom determinable from a runs test, whereas MDA must use an average number (from previous studies determined empirically to be at about one-third the developmental sample size or roughly crediting only one observation a day as independent). Most of these additional selected predictors explain a significant amount of variability in the low ceiling and visibility categories.

Another adjustable factor is that of minimum frequency in the number of observations for a possible predictor (in our terminology "bit count"). In order for a predictor to be selected it must have been observed at least a minimum number of times in the developmental sample. This is an adjustable input parameter to the

program*. A more detailed discussion on its effects is given in a subsequent experiment. Suffice it to say that for larger values it selects more stable predictors with a tendency toward predictor selection to favor higher ceiling and visibility categories. An additional effect is that for larger values it would select fewer predictors thus offsetting some of the effects due to the degrees of freedom factor.

2) A summary of the results shows MDA with ten asterisks in its favor while REEP has eight. In almost every instance where an individual \bar{P} score or the number of hits differ this difference is very small. We conclude that for all practical purposes MDA and REEP produce comparable results.

*The present MDA program now has this as an input parameter. At the time of the Atlantic City and Offutt comparisons it was not available.

	REEP	.1402*

Asterisks are used to denote superiority.

Purpose

A test to compare the results obtained when the predictor variables are in raw dummy form to those obtained when the predictor dummies are in cumulative form.

Predictands

Predictands used in this experiment were the Atlantic City ceilings for periods of 2, 5, and 7 hours in advance. These three predictands were divided into five intervals according to the operationally significant categories of ceiling, as shown in Table 2-1. Specifications for each predictand are shown in Table 2-2.

Predictors

Seven meteorological elements at ten predictor stations (see Figure 2-1) plus the time of day (TOD) and day of year (DOY) variables were transformed into dummy variables by dividing each predictor element into a number of intervals or categories (Table 2-3).

Data Sample

The data used for this experiment is the same as was used for Experiment No. 1, consisting of 10,000 observations selected randomly from the ten-year period from 1 January 1949 to 31 December 1958. The developmental sample consists of 7956 observations from the first eight years and the verification or independent sample contains 2044 observations from the last two years.

The set of 450 standard form dummy predictors are shown in Table 2-3. Table 2-4 tabulates the cumulative dummy predictors. Table 2-5 gives the specifications and limits of the dummy variables when used in the standard form and Table 2-6 gives similar information when the predictors are in the cumulative dummy form. Predictions using REEP were made for Atlantic City ceiling at 2, 5, and 7 hours in advance using the standard dummies and the cumulative dummies separately.

Results

The dummy predictors selected by REEP are shown in Tables 2-7a to 2-7f, as well as the REEP regression equation coefficients for each group of the predictand. Results of the forecasts using the two sets of predictors are shown in the contingency tables (Tables 2-8a to 2-8c) for the independent sample. Also shown are the results using persistence. The number of correct forecasts (hits), the Brier and Allen \bar{P} scores, and the individual group contributions to the overall \bar{P} score are given below each contingency table. The number of hits and overall \bar{P} scores are summarized in Table 2-9.

Conclusions

From these limited results there does not appear to be any reason to prefer one form of dummy variables over the other.

Definition of Predictand Groups for Atlantic City Municipal Airport

Group
Number

EXPERIMENT 3. Nullifying the Effect of High Ceilings in Predictor Selection.

Purpose

To determine the effect on the forecast of assuming a zero degree of freedom for category 5 of the ceiling predictand.

Procedure

Forecasts were made for ceiling at Atlantic City 3 hours and 7 hours in advance. The degrees of freedom specified for categories 1 through 4 of the ceiling predictand was specified as 2652, the number normally used for the Atlantic City developmental sample size of 7956, or one-third of the total developmental sample. The degrees of freedom for category 5 of the ceiling predictand was specified as zero. This in effect eliminated the possibility of having category 5 affect the selection of any predictor.

Data Sample

The ten years of data from 1 January 1949 to 31 December 1958, consisting of 10,000 observations selected at random was used in this experiment. The developmental sample consisted of 7956 observations from the first eight years and the verification or dependent sample of 2044 was from the last two years of the data sample.

Predictands

The ceiling at time intervals of 3 and 7 hours in advance were the predictands for this experiment. The operationally significant categories for which the forecasts were made are shown in Table 3-1. The specifications are shown in Table 3-2.

Predictors

The set of 423 dummy predictors used in Experiment No. 1 for the 13-station Atlantic City network was used for this experiment (see Figure 1-1 and Tables 1-3 and 1-4).

Results

The predictors selected by REEP for each of the predictands are given in Tables 3-3a and 3-3b, as well as the coefficients in the REEP regression equation for each group of the predictand. Contingency tables showing the forecast-versus-observed frequencies for REEP with zero degree of freedom in category 5 and for persistence are shown in Tables 3-4a and 3-4b. The number of correct forecasts (hits), the Brier and Allen \bar{P} scores, and the individual group contributions to the overall \bar{P} score are shown.

Table 3-5 summarizes the hits and \bar{P} scores and compares them with the results using the regular degree of freedom for all categories of the predictand as determined by Experiment No. 1.

Conclusions

The results in this experiment are the same or slightly worse than those using the regular degrees of freedom, both with regard to \bar{P} score and hits as well as with regard to better predicting the low categories. It is therefore concluded that modifying the degrees of freedom within the higher categories does not appreciably change the results from those obtained using the regular degrees of freedom. The lack of success in this effort to force the selection of predictors which contribute to improving the forecasts of low ceiling conditions suggests that the regular selection method is performing this function satisfactorily.

EXPERIMENT 4. Ceiling Prediction Using Persistence with One and Two Hour Lagged Persistence.

Purpose

A test on the predictability of persistence when time variations in persistence are made available.

Predictands

Predictands chosen for this experiment were ceilings at 1, 2, and 3 hours in advance. The operationally significant categories for which the forecasts were made are shown in Table 4-1. The specifications for the predictands are shown in Table 4-2.

Predictors

All the possible combinations of the five categories of ceiling for Atlantic City at the three time periods: 1) time of observation, 2) time of observation minus one hour, and 3) time of observation minus two hours, were used in combinations of logical "ANDS" and logical "ORS" to form 400 predictors. These 400 predictors plus the 15 ceiling dummies for the three different time periods gave a total of 415 predictors, made up only of ceiling dummies for only one station--Atlantic City. The intervals for the five categories of ceiling used as predictors are the same as those for the predictands shown in Table 4-1.

Data Sample

Standard hourly airways surface observations covering the ten year period, 1 January 1949 to 31 December 1958, furnished the data for this study. The developmental sample of 7956 observations is a random selection from the first eight years and the verification sample of 2044 observations is a random selection from the last two years. Note: This sample is not the same as in previous experiments because lagged predictors were involved.

Results

The predictors selected by REEP for each of the three predictands are given in Tables 4-3a to 4-3c. Also shown are the REEP regression equation coefficients for each group of the predictand.

Contingency tables showing the forecast-versus-observed frequencies for each of the three forecasts, and comparing the results using REEP to the results using persistence (without lags) is shown in Tables 4-4a to 4-4c. The number of correct forecasts (hits) and the Brier and Allen \bar{P} scores as well as the individual group contributions to the overall \bar{P} score are shown below each contingency table. The number of hits and the overall \bar{P} scores are summarized in Table 4-5.

Conclusions

The 415 possible predictors exhaust the ways in which persistence with lags could improve the forecast. Contrary to common belief the results of this experiment show there is little improvement over persistence when lagged persistence is made available for selection.

EXPERIMENT 5. Multiple Predictands Processed Simultaneously.

Purpose

To investigate the selection of predictors for more than one predictand at a time in an attempt to reduce the number of analysis runs ordinarily required.

Procedure

Four REEP selection runs were performed using the following pairs of predictands as the predictand:

- 1) Ceiling plus 3 hours and visibility plus 3 hours
- 2) Ceiling plus 3 hours and ceiling plus 7 hours
- 3) Visibility plus 3 hours and visibility plus 7 hours
- 4) Ceiling plus 7 hours and visibility plus 7 hours

Predictors consisted of dummy (zero-one) variables of seven meteorological elements from a thirteen-station network (see Figure 1-1). The predictors selected from those runs were compared with those selected when the predictands were run singly. This comparison is shown in Table 5-1. The predictors selected when the predictands were run singly are indicated by an x under the appropriate ceiling or visibility predictand.

Predictands

The five operationally significant categories of ceiling and visibility for the predictands are shown in Table 5-2. The specifications of the predictands are listed in Table 5-3.

Predictors

The 423 predictors used in this experiment are the same as those used in Experiment No. 1 (see Tables 1-3 and 1-4).

Data Sample

Standard hourly airways surface observations covering the ten year period, 1 January 1949 to 31 December 1958, constituted the data used in this study. The developmental sample of 7956 observations is a random selection from the first eight years and the verification sample of 2044 observations is a random selection from the last two years.

Results

Contingency tables (Tables 5-4a and 5-4b) were formed to show the forecast-versus-observed frequencies for the 3-hr predictions of ceiling and visibility using the predictors selected by REEP when the predictand was a single predictand and also when the predictand was a pair of predictands. The number of correct forecasts (hits) and the Brier and Allen \bar{P} scores as well as the individual group contributions to the overall \bar{P} score are given below each contingency table.

Conclusions

There is sufficient redundancy in the predictands such that selection of predictors may be made on more than one predictand at a time. This applies even though they differ with regard to meteorological element or with regard to time leads. These conclusions were drawn from the fact that the predictors selected, when the predictands were processed singly, are all essentially among those selected when they are considered jointly. The one direct comparison for which results on independent data were obtained (Ceiling 3 hrs and Visibility 3 hrs) confirms this surmise.

EXPERIMENT 6. Effect of Restricting Selection to Predictors with
Certain Minimum Occurrence Frequencies.

Purpose

This experiment was conducted to determine in a general way if there was any optimum limit to the number of occurrences to be permitted in a predictor before REEP would be allowed to include that predictor among those selected.

Procedure

Forecasts were made for 3-hr and 7-hr ceiling and visibility at Atlantic City Airport. Three different minimum number of occurrences of the predictors were specified in the separate runs, except for ceiling three hours in advance, which was tested for only two. The number of occurrences of the predictors specified were 10, 50, and 100. In the first case any predictor must have occurred at least ten times before it could be considered by REEP for selection, and similarly for the cases of 50 and 100. The forecasts made using the predictors selected by REEP in each case were then compared to determine the most favorable minimum occurrence frequency, comparing the \bar{P} score and the number of correct forecasts in each case.

Data Sample

The developmental sample of 7956 observations is a random selection of hourly surface observations from the eight year period from 1 January 1949 to 31 December 1956. The verification sample of 2044 observations is a random selection from the two year period from 1 January 1957 to 31 December 1958. Observations are included in this sample for the 13 stations comprising this Atlantic City Airport network (Figure 1-1).

Predictands

Table 6-1 shows the five operationally significant categories of ceiling and visibility for the predictands used in this experiment. The specifications of the predictands are shown in Table 6-2.

Predictors

The 423 original dummy predictors used in this experiment are the same as those used in Experiment No. 1 (see Tables 1-3 and 1-4). The predictors with number of occurrences less than 100 are listed in Table 6-3. There are 90 such dummy predictors out of a total of 423. The number of observations in the developmental sample, as noted previously, is 7956.

Results

Contingency tables (Tables 6-4a to 6-4d) were formed to show the forecast-versus-observed frequencies for the 3-hr and 7-hr predictions of ceiling and visibility using the predictors selected by REEP when the conditions of 10, 50, and 100 occurrence minimum were applied to the selection procedure. The number of correct forecasts (hits) and the Brier and Allen \bar{P} scores as well as the individual group contributions to the overall \bar{P} score are given below each contingency table. The number of hits and the overall \bar{P} scores are summarized in Table 6-5.

Conclusions

The results suggest that, when selection is restricted to predictors with a larger number of occurrences, the predictors are as good or better than those when restricted by fewer number of occurrences. In addition, there is no apparent deterioration in the ability to forecast low conditions by this restriction.

EXPERIMENT 7. Single-Station Predictors: Raw Dummies and Boolean Combinations.

Purpose

To investigate the accuracy of forecasts using only single-station predictors. In the event the accuracy is sufficiently competitive, a generalized operator might be developed where spacial analyses of network parameters would not be required.

Procedure

From the 423 predictors used in the Atlantic City network of 13 stations (see Table 1-3), the 55 predictors for only Atlantic City predictors (not including TOD and DOY) were extracted. Selections and predictions were first made for ACY ceiling and visibility for three and seven hours using the 55 dummy predictors alone.

Next, those dummy predictors with 400 or more occurrences were then formed into all possible combinations of pairs joined by a logical "AND" including the combination of each predictor with itself. An exception to this procedure was made in figuring the number of occurrences under the Weather Element heading. In this case the weather dummies from 2 to 8 (precipitation) were grouped together to represent a precipitation predictor. Combining the dummy predictors in this way resulted in the formation of 467 new predictors. Selections and predictions were again made for ACY ceiling and visibility at three and seven hours in advance using the 467 Boolean-paired predictors. The results were compared with those from the prediction runs with the raw dummy predictors, as well as with the results using all the network predictors (Experiment No. 1).

Predictands

The predictands, as used in the earlier experiments, are subdivided into five operationally significant intervals of ceiling and visibility as shown in Table 7-1. The specifications of the predictands are shown in Tables 7-2a and 7-2b.

Predictors

As noted previously the predictors used in this experiment were extracted from the 423 predictors used in the Atlantic City network of 13 stations. The 55 dummy predictors used in the first prediction runs are shown in Table 7-3 together with the number of occurrences of each in the developmental sample of 7956 observations. Table 7-3 also lists the specifications and limits of the dummy variables. Those predictors with 400 occurrences or more, plus the time of day (TOD) and day of year (DOY), were formed into all possible pairs joined by a logical "AND" resulting in 467 Boolean-paired predictors.

Data Sample

As in the earlier experiments the 10,000 observations used in this experiment were randomly selected from the ten year period 1 January 1949 to 31 December 1958. The developmental sample has 7956 observations from the first eight years of the ten year period, and the verification sample has 2044 observations from the last two years.

Results

The four sets of predictors selected by REEP, using the 55 predictors for ACY are listed in Tables 7-4a to 7-4d. The predictors selected using the 467 Boolean-paired predictors are shown in Tables 7-5a to 7-5d. Also shown in each of these tables are coefficients in the REEP

regression equation for each group of the predictand. Contingency tables (Tables 7-6a to 7-6d) show the forecast-versus-observed frequencies for the 3-hr and 7-hr predictions of ceiling and visibility using the 55 dummy predictors for ACY listed in Table 7-3 and also using the 467 Boolean combination of predictors previously described. The number of correct forecasts (hits) and the Brier and Allen \bar{P} scores as well as the individual group contributions to the overall \bar{P} score are given below each contingency table. Tables 7-7a and 7-7b summarize the hits and \bar{P} scores for this experiment. In addition, these tables show how the results of this experiment compare with those of Experiment No. 1, in which all the dummy predictors for the 13 station Atlantic City network were used, and with the results of a straight persistence forecast.

Conclusions

- 1) The single-station raw dummy predictors give results which are better than persistence.
- 2) The single-station Boolean predictors are as good or better than the raw predictors except for the \bar{P} score in predicting 3-hr ceiling. Low conditions are forecast more often and more accurately with Boolean predictors.
- 3) Although the selected network predictors are quite a bit better than either single-station set of predictors, the Boolean set is consistently better than the network in predicting visibility.
- 4) The results are sufficiently encouraging to suggest that more work be done. In addition, it seems worth attempting to combine the set of network and Boolean predictors in a separate experiment (see Experiment No. 8).

EXPERIMENT 8. Combination of Selected Predictors from Network and Single-Station Boolean.

Purpose

To determine the extent of the improvement in the forecast when using the combined predictors selected by two separate methods.

Procedure

The 58 predictors selected by REEP in the four selection runs (CIG + 3 hrs, CIG + 7 hrs, VIS + 3 hrs, VIS + 7 hrs) using all the dummy predictors of the 13-station Atlantic City network (see Experiment No. 1) were combined with the 53 single-station predictors selected using the Boolean-paired predictors of the forecast station (see Experiment No. 7). Eliminating the duplication of predictors selected in these two ways resulted in 78 predictors, which were used in this experiment (Table 8-3). Four prediction runs were made and the results compared with the results using the network predictors (Experiment No. 1) and the Boolean-paired predictors (Experiment No. 7).

Predictands

As before, the predictands are divided into five operationally significant intervals of ceiling and visibility (Table 8-1). The specifications of the predictands are listed in Table 8-2.

Predictors

The 78 predictors used in this experiment are shown in Table 8-3, with the number of occurrences of each in the developmental sample of 7956 observations also shown. The specifications and limits of the dummy variables are as previously indicated in Table 1-4.

Data Sample

The data sample consists of 10,000 observations selected at random from the ten-year period, 1 January 1949 to 31 December 1958. The developmental sample consists of 7956 observations from the first eight years of the data sample and the verification sample consists of 2044 observations from the last two years of the ten-year period.

Results

The predictors selected by REEP for the four selection runs are shown in Tables 8-4a to 8-4d. The REEP regression equation coefficients for each group of the predictand is also shown. Contingency tables (Tables 8-5a to 8-5d) show the forecast-versus-observed frequencies for the 3-hour and 7-hour predictions of ceiling and visibility using the combined predictors as previously described. The number of correct forecasts (hits), the Brier and Allen \bar{P} scores, and the individual group contributions to the overall \bar{P} score are given. The comparison of the hits and the \bar{P} scores achieved by these combined predictors with the hits and \bar{P} scores of the network predictors alone, and the Boolean-paired single station predictors alone, is shown in Table 8-6.

Conclusions

The results of this combined study are a decided improvement over either the network or the single station Boolean predictors taken separately. This suggests that Boolean predictors generated between network variables might even improve upon the results obtained in the present combination.

Table 8-1

Definition of Predictand Groups for Atlantic City Municipal Airport

<u>Group Number</u>	<u>Ceiling Intervals</u>
1	0 ft \leq Ceiling < 200 ft
2	200 ft \leq Ceiling < 500 ft
3	500 ft \leq Ceiling < 1000 ft
4	1000 ft \leq Ceiling < 3000 ft
5	3000 ft \leq Ceiling

<u>Group Number</u>	<u>Visibility Intervals</u>
1	0 mi \leq Visibility < 1/2 mi
2	1/2 mi \leq Visibility < 1 mi
3	1 mi \leq Visibility < 2 mi
4	2 mi \leq Visibility < 3 mi
5	3 mi \leq Visibility

5.0 DISCUSSION

The REEP procedure has the following features to recommend its use over MDA:

Feature 1: The series of G regressions in REEP need not be restricted to mutually exclusive or exhaustive events as in MDA. Thus, any combination of conditions may be done simultaneously. For example, the following series of predictand elements might be considered in a single REEP analysis, where $G = 15$.

Y_1 = equal to unity if $0 \text{ ft} \leq \text{ceiling} < 200 \text{ ft}$

Y_2 = equal to unity if $200 \text{ ft} \leq \text{ceiling} < 500 \text{ ft}$

Y_3 = equal to unity if $500 \text{ ft} \leq \text{ceiling} < 1000 \text{ ft}$

Y_4 = equal to unity if $1000 \text{ ft} \leq \text{ceiling} < 1500 \text{ ft}$

Y_5 = equal to unity if $1500 \text{ ft} \leq \text{ceiling}$

Y_6 = equal to unity if $0 \text{ mi} \leq \text{visibility} < 1/2 \text{ mi}$

Y_7 = equal to unity if $1/2 \text{ mi} \leq \text{visibility} < 1 \text{ mi}$

Y_8 = equal to unity if $1 \text{ mi} \leq \text{visibility} < 2 \text{ mi}$

Y_9 = equal to unity if $2 \text{ mi} \leq \text{visibility} < 3 \text{ mi}$

Y_{10} = equal to unity if $3 \text{ mi} \leq \text{visibility}$

Y_{11} = equal to unity if $\begin{array}{l} 0 \text{ ft} \leq \text{ceiling} < 200 \text{ ft} \\ \text{or} \\ 0 \text{ mi} \leq \text{visibility} < 1/2 \text{ mi} \end{array}$

Y_{12} = equal to unity if $\begin{array}{l} 200 \text{ ft} \leq \text{ceiling} < 500 \text{ ft} \\ \text{or} \\ 1/2 \text{ mi} \leq \text{visibility} < 1 \text{ mi} \end{array}$

Y_{13} = equal to unity if $\begin{array}{l} 500 \text{ ft} \leq \text{ceiling} < 1000 \text{ ft} \\ \text{or} \\ 1 \text{ mi} \leq \text{visibility} < 2 \text{ mi} \end{array}$

Y_{14} = equal to unity if $1000 \text{ ft} \leq \text{ceiling} < 1500 \text{ ft}$
or
 $2 \text{ mi} \leq \text{visibility} < 3 \text{ mi}$

Y_{15} = equal to unity if $1500 \text{ ft} \leq \text{ceiling}$
or
 $3 \text{ mi} \leq \text{visibility}$

This feature has been made use of in Experiment 5.

Feature 2: Predictor selection in REEP is not biased by the group frequencies as is the case in MDA predictor selection. This is because each predictand variable (e.g., Y_1, Y_2, \dots, Y_G) is considered separately and distinctly during selection. Most importantly, at the time of termination of selection, the significance test says there is no predictor able to provide a significant contribution to any one of the G predictand variables. For example, if the series of predictand variables is the usual five ceiling categories then predictors able to discriminate category 1 (ceiling $< 100 \text{ ft}$) are being considered on an equal basis with those able to discriminate category 5 (ceiling $\geq 1500 \text{ ft}$). Another important feature in REEP selection is that the effective degrees of freedom, after account is taken of serial correlation, may be determined for each predictand variable separately and distinctly. For example, high ceiling conditions have a very high serial correlation (low effective degrees of freedom for nearly consecutive observations) whereas low ceiling conditions have a low serial correlation (high

effective degrees of freedom for consecutive observations). The facility to avoid the use of an average, as is unfortunately required in MDA, aids somewhat in selecting predictors having discriminatory information regarding the low conditions.

Feature 3: The mode of calculation in the REEP procedure has an additive structure in place of the multiplicative structure in MDA. That is, for both development and operational use REEP needs only the logical and arithmetic operations of addition which are faster relative to the arithmetic operations of multiplication required in the distance neighborhood portion of MDA. This has a decided effect on the speed with which both the statistical development and operational forecasting may be performed using the two techniques. The factor is in favor of REEP over MDA by about four to one (confirmed) in development and by 300 to one (estimated) in making operational forecasts.

Feature 4: It appears that REEP permits physical and synoptic interpretation of the selected predictors and the effect each has on the probability of the event being forecast. For example, in Experiment 1 (Table 1-5c) it can be seen that if the 9th predictor is a one (condition PHL ceiling < 200 ft is being observed) then .183 is added to the probability that the visibility condition three hours hence will be < 1/2 mile, whereas the other visibility categories add or subtract the following probability amounts: .018, -.079, -.084, and

-.039. However, the danger still exists for misinterpretation as a result of intercorrelation among predictors.

Feature 5: In operational forecasting, the REEP procedure can deal more efficiently than MDA with the problem of missing data or with previously unobserved weather combinations. The reason for this is that the output from REEP is a set of IBM cards containing a series of regression equations and a matrix and vector of crossproducts. If the value of a predictor variable is unavailable for making an operational forecast, a new equation omitting the missing predictor value may be generated from the output information. This operation takes very little time on a computer even when more than one predictor value is missing. MDA on the other hand has to have a matrix diagonalization performed to account for the missing predictor or predictors. In addition, discriminant functions must be calculated for the entire developmental sample of data. In REEP there is obviously no difficulty in making a prediction when the combination of predictors is not observed in the developmental sample. However, in MDA the output (on magnetic tape) is a table within which all predictor combinations observed in the developmental sample are given with the corresponding probability forecasts. When a new combination of events arises probabilities must be determined using distance neighborhood. The frequency of occurrence is about one out of every ten operational forecasts. This requirement is very

time consuming making it much less efficient than REEP
in those instances.

6.0 FUTURE WORK

The most profitable single item for future effort is the modification of the prediction model so as to introduce some form of nonlinear capability. A suitable approach to this problem has already been suggested by J. G. Bryan¹. The model consists of a linear exponential function which restricts the probability estimates to the interval (0,1). An additional feature of this model is that it uses the present REEP selection method to obtain a set of selected predictors and the REEP procedure to form a first estimate of the required coefficients. It therefore does not require an extended developmental period before it can be tested.

Another area for possible future work is a study of the selection criterion employed by REEP. The MDA criterion has been the subject of extensive research. Several possible alternatives are available and some have been looked into but none have been subjected to a fair comparison with the present method.

A combination of MDA and REEP to form a somewhat different forecast system should also be considered. This consists of applying the REEP method to the points enclosed in the Fix-Hodges neighborhood used by MDA. The purpose of this approach would be to replace the relative frequencies, now used as probabilities within the neighborhood, by the REEP estimates. While a detailed discussion of this method cannot be included here, it can be reported that this has been done for some selected cases with results which are quite encouraging.

¹ Bryan, J. G., 1963: Parametric estimation of probabilities in multiple group classification. Unpublished manuscript. The Travelers Research Center, Inc., 13 pp.

et

The matter of transforming continuous predictors to dummy predictors needs further investigation. Considerations include: means for introducing as much synoptic and/or dynamic information as possible into the dummies; experimentation with different logical combinations of the dummies; the effect of suppressing the within class variance of the continuous predictors which is an integral part of the dummifying process; and the forcing of a complete set of dummies onto the selection program whenever one of the sets is selected.

In the area of application of the technique many experiments remain to be carried out to determine its characteristics on different predictands and different data. The possibility of selecting a single set of predictors applicable to several predictands distributed either in space or in time has not been thoroughly explored. Several more parameters remain to be tested for both prediction and specification. Attempts to make predictions of continuous variables by increasing the number of predictand groups is also worth investigating. In summary, a great deal of work remains to be done in the application area.

7.0 ACKNOWLEDGEMENTS

Development of the REEP procedure was substantially aided by the efforts of Mr. Thomas G. Johnson. Programming of REEP for the IBM-7090 was performed by Mr. Johnson, Miss Edna L. Sorenson, and Miss Katherine Fogarty. Mr. Karl A. Abrahamson assisted in the preparation of the report. The manuscript was typed by Mrs. Edward Miller. The author is grateful to all of these individuals.
